

Apex Corruption causes Violent Protests*

Roberto González-Téllez[†] Saumitra Jha[‡] Eduardo Rivera[§] Enrique Seira[¶]

This draft: 2026-07-31

Abstract

We document that *apex* corruption scandals—corrupt acts implicating top-level politicians—cause immediate and persistent increases in violent protests. Using a panel of 176 corruption scandals across 23 countries in Latin America from 2008 to 2018, merged with daily protest counts, we show that the daily count of violent protests rises sharply after scandals implicating a President or Other Apex official—by about 0.06 protests per country-day in the month following disclosure, roughly 1.7 times the pre-scandal baseline—while scandals implicating non-apex officials produce no such immediate response, and a pooled test rejects equality of the two effects. The response appears within a week of disclosure and persists even in a four month window. It is specific to apex corruption: neither football match losses nor currency depreciations, two other high-salience national shocks, move violent protests. Our findings identify a high-frequency, high-magnitude channel through which corruption shapes the political environment in democracies.

*We thank seminar audiences and colleagues for helpful comments. All errors are our own.

1 Introduction

Political violence is among the most consequential outcomes a democracy can experience. Civil unrest disrupts economic activity, displaces investment, and—when met with state violence in return—erodes the social contract that legitimizes the regime. An influential economic literature has linked political violence to economic shocks (Miguel et al. 2004; McGuirk and Burke 2020), to commodity rents and network structure (König et al. 2017; Dube and Vargas 2013), to the foundations of state capacity (Besley and Persson 2011), and in recent work to abrupt withdrawals of foreign assistance (Rohner et al. 2026). Related work shows that protests themselves can produce durable political effects (Madestam et al. 2013; Bursztyn et al. 2021). The contribution of political shocks to events that change citizens’ beliefs about who governs them, however, has received considerably less attention. In this paper we argue that disclosures of apex corruption are one such shock, and that the behavioral consequences for political violence are large, immediate, and persistent.

Corruption has been long studied, with known costs for growth and public goods provision (Mauro 1995; Treisman 2007; Olken 2007; Olken and Pande 2012; Glaeser and Saks 2006). In the past two decades, citizens’ perceptions of corruption prevalence have risen (Cantoni et al. 2024), and corruption scandals associated to *apex* politicians have drawn more attention from news outlets in recent years (Rivera et al. 2024); perhaps unsurprisingly due to the expansion of social media, which reduces the cost of diffusing information and enables news outlets to reach broader audiences (Enikolopov et al. 2018; Tufekci 2024; DellaVigna and Kaplan 2007). Even though exposing corruption scandals on news outlets can have positive desired effects, such as political accountability or crackdowns of corruption networks (Ferraz and Finan 2011a; Arias et al. 2019, 2022), it can also have negative undesired effects on democratic values (Ajzenman 2021; Rivera et al. 2024) and away from the polling booths. Public exposure of malfeasance by sitting officials changes what citizens believe about who governs them and about the rules under which the government operates. The most consequential corruption-related political moments of the last decade, such as Brazil’s Lava Jato¹, were mobilization events, not electoral ones.

We document that apex corruption—corrupt acts implicating top-level politicians—triggers immediate and persistent increases in violent protests. Using a hand-curated panel of 176 corruption scandals across 23 Latin American countries from 2008 to 2018, merged with daily protest counts from the Mass Mobilization (MM) project (Clark and Regan 2016), we establish four facts. First, the daily count of violent protests rises sharply following scandals implicating a President or Other Apex official, while the count of peaceful protests is largely unaffected; scandals implicating Congressmen,

¹See [this video](#) for more information on the scandal.

lower judiciary, and other non-apex officials leave protest patterns broadly unchanged, and we can reject that the two effects are equal. Second, the effect appears within a week of disclosure and the point estimate remains positive even four months later, with no evidence of pre-trends. Third, the response is specific to apex corruption: neither national-team football losses (see e.g., Depetris-Chauvin et al. 2020) nor currency depreciations—two other high-salience, plausibly as-good-as-randomly-timed national shocks—move violent protests. Fourth, exploring heterogeneity by the 2008 level of democracy, the response is present across countries and, if anything, somewhat larger and more persistent in higher-democracy countries, though the high- versus low-democracy difference is not statistically significant.

2 Method

2.1 Study Design and Measures

Our empirical analyses exploit the randomness of corruption scandal disclosures in Latin American news outlets between 2008 and 2018. In particular, we use an interrupted time-series design in which we compare protest occurrences in countries with scandals before and after the scandal occurs. Our analysis dataset is created by: (i) Scraping the Twitter accounts from news outlets in Latin America to identify the calendar date in which a scandal in a given country is first reported², (ii) create an event-window of $T \in \{30, 120\}$ days before and after the scandal, (iii) merge the country-day count of protests from the MM data to create a ‘scandal-protest’ dataset for a given country in a given calendar-date window, and lastly, (iv) append all such scandal-protest datasets to build the analysis dataset.

The MM dataset is available for the period 1990–2020, and it includes information on the date, size, and location of any episode in which 50 or more protesters publicly demonstrate against the State. If a protest lasts X days, we code the occurrence of a protest at date $t, t+1, \dots, t+X-1$. If the same protest is associated with more than one date (e.g., because the news source for the protest cannot accurately identify whether it is a continued or a new protest), then we keep the date of the earliest protest. For a protest to be classified as “violent”, “[t]he violence could include anything from riotous behavior that destroys property to shooting at the police or military” (Clark and Regan 2016). Our main outcome is the number of protests occurring in a given country-date. We focus on the years 2008–2018, given that our corruption scandals data is available for those years.

Importantly, our recollection of scandals allows us to identify the position of the implicated politician. We then look at the scandals and manually classify them in three categories: (i) “President” includes

²We keep the date of the first news report to (a) be able to estimate the effect of a scoop, and (b) avoid double-counting a scandal due to follow-up news reports on it.

scandals in which the implicated official is a President (current or former), (ii) “Other Apex” includes scandals in which the implicated official is either a Governor or Supreme Court Justice, and (iii) “Non-Apex” includes scandals in which the implicated official is a Congressman, lower judiciary, or other lower-rank officials. Throughout, we group the President and Other Apex scandals together (“apex”; 63 scandals) and contrast them with the Non-Apex scandals (113 scandals).

We use Ordinary Least Squares (OLS) to estimate the following equation on each of our Apex and Non-Apex samples:

$$Y_{c(s)t} = \beta \mathbb{1}\{t \geq \text{Scandal Date}_{c(s)}\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t} \quad (1)$$

where α_d denote day of the week fixed effects, λ_m denote month of the year fixed effects, θ_{cy} denote country-year fixed effects, $\text{Scandal Date}_{c(s)}$ is the date in which corruption scandal s in country c occurs, Y_{ct} denotes the outcome of interest in country c at date t , and $\varepsilon_{c(s)t}$ is an idiosyncratic error term.

To trace dynamics we replace $\mathbb{1}\{t \geq \text{Scandal Date}_{c(s)}\}$ in Equation 1 with a saturated set of 30-day bin indicators for four months before/after the scandal. The reference category in each time-to-event graph is the bin immediately before disclosure (i.e., $w_{s,t} \in [-30, -1]$).

The identification assumption we rely on for our estimates to be interpreted as causal is that conditional on country-year, month-of-year, and day-of-week fixed effects, the within-year date of disclosure of a scandal is as-good-as-randomly assigned in relation to the protest baseline of the country. The country-year fixed effects absorb every source of country-year-level confounding such as pre-existing political instability, electoral calendars, or institutional reforms. The day-of-week and month-of-year fixed effects absorb weekly and seasonal cycles in protest activity.

3 Results

3.1 Apex corruption increases violent protests

Table 2 reports OLS estimates of the post-scandal effect on violent and peaceful protests, split by the political rank of the implicated official. Panel A restricts the sample to Apex scandals; Panel B restricts to Non-Apex scandals. Each panel reports eight outcome–window cells: violent and peaceful protest *counts* on the ± 30 - and ± 120 -day windows, and the corresponding violent/peaceful *shares*³. The contrast is stark. In the Apex panel, the daily count of violent protests rises by 0.060 per country-day

³We define the share outcomes at the country-day level by dividing the number of violent (peaceful) protests by the total protests, and impute a 0 if there are no protests in a given day. Given that there is only one protest in most cases for country-days in which there is mobilization, our outcomes are highly correlated and the corresponding estimates are very similar.

in the ± 30 -day window ($p < 0.01$)—about 1.7 times the pre-scandal baseline of 0.036—and by 0.021 in the ± 120 -day window ($p < 0.1$). In the Non-Apex panel the immediate (± 30 -day) violent effect is essentially zero (0.000), with only a smaller, delayed increase of 0.016 at the ± 120 -day horizon ($p < 0.05$). Strikingly, peaceful protests move little in either panel at either horizon.

To make the Apex-vs-Non-Apex contrast explicit, Table 1 pools the two subsamples into a single specification and formally tests whether the post-scandal effect differs between them. For each outcome and window we estimate

$$Y_{c(s)t} = \beta_{\text{Apex}} \text{Post}_{st} \mathbf{1}\{\text{Apex}_s\} + \beta_{\text{NA}} \text{Post}_{st} \mathbf{1}\{\text{Non-Apex}_s\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t},$$

where Apex_s ($\text{Non} - \text{Apex}_s$) indicates a Apex (Non-Apex) scandal, and the row “ p -value: Pres+Other Apex = Non-Apex” reports the two-sided p -value for $H_0 : \beta_{\text{Apex}} = \beta_{\text{Non-Apex}}$. In this pooled specification the immediate (± 30 -day) violent-protest effect is 0.048 for apex scandals ($p < 0.01$) versus -0.003 for non-apex scandals, and we reject equality of the two ($p = 0.020$). At the ± 120 -day horizon both are positive (0.022 for apex, $p < 0.05$; 0.012 for non-apex), though they are no longer statistically distinguishable ($p = 0.411$). The *immediate* violent response to corruption is thus concentrated among apex scandals.

Table 1. Apex scandals cause violent mobilization while Non-Apex scandals do not.

OLS estimates of β_{Apex} and $\beta_{\text{Non-Apex}}$ from the pooled specification above, on the same eight outcome–window cells as Table 2. The row “ p -value: Pres+Other Apex = Non-Apex” reports the two-sided p -value for $H_0 : \beta_{\text{Apex}} = \beta_{\text{Non-Apex}}$. Standard errors in parentheses are clustered at the country $\times$ year $\times$ day-bin level. Same fixed effects and sample period as Table 2. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

3.2 Protest dynamics around apex corruption scandals

Figure 1 traces the dynamics of the effect, replacing the post-scandal indicator with a fully saturated set of 15-day event-time bin indicators over the ± 60 -day window, and estimated separately on the two

subsamples of Table 2. In the Apex subsample, violent protests (Figure 1a) show arguably no pre-trend and then jump at disclosure, remaining elevated in the month that follows before converging back to the pre-scandal levels; peaceful protests (Figure 1b) show no immediate increase, but they do however slightly increase in the months that follow, though by a small magnitude. In the Non-Apex subsample, violent protests (Figure 1c) do not increase by large amounts with scandal disclosures, and the response is delayed. Overall, Non-Apex scandals cause no effects—positive or negative—on peaceful protests (Figure 1d). The absence of a pre-trend in every panel supports the identifying assumption that the within-year timing of disclosure is as good as random relative to the protest baseline.

Figure 1. Protest dynamics: Apex vs. Non-Apex (± 60 -day window, 15-day bins).

OLS event study estimated *separately* on the Apex and Non-Apex subsamples, replacing the post-scandal indicator with a saturated set of 15-day event-time bin indicators over the ± 60 -day window (Equation 1). The four panels are violent and peaceful protests $\times$ Apex and Non-Apex; the bin immediately preceding disclosure ($w_{s,t} \in [-15, -1]$) is the omitted reference and the faint vertical band marks the disclosure cutoff. All four panels share a common y-axis. Vertical bars are 90% confidence intervals; standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.

3.3 The protest response is specific to apex corruption

Is the violent-protest response a general reaction to salient national news, or is it specific to apex corruption? To answer this question, [Table 2](#) benchmarks the corruption effect against two other high-salience national shocks whose timing is plausibly as-good-as-random with respect to the protest baseline: national-team football (soccer) match losses and currency depreciation episodes. Each shock is estimated using [Equation 1](#) and the same eight outcome–window columns (counts and shares), but changing the post-scandal indicator for an indicator of a national football team loss, or a month-to-month depreciation of the exchange rate of more than 5%. The table reproduces Panels A and B of [Table 2](#) so that both headline corruption regressions can be read directly against the two benchmarks. The apex-corruption effect on violent protests in the ± 30 -day window (0.060, $p < 0.01$) is an order of magnitude larger than—and statistically unlike—the corresponding football (0.006) and currency-depreciation (0.004) estimates, neither of which is distinguishable from zero. The mobilization response is thus specific to apex corruption, not a generic reaction to salient national events.

3.4 Heterogeneity by the level of democracy

A natural question is whether these patterns of mobilization are driven by the country’s democratic environment. There are at least two related, yet opposite, hypotheses about how democratic level of a country interacts with mobilization patterns. On the one hand, citizens in countries with higher levels of democracy may not mobilize, since strong democratic institutions in their countries can punish corrupt officials and remove them from office once proven guilty. On the other hand, precisely because citizens in highly democratic countries have higher standards for accountability, they may choose to mobilize in order to call democratic institutions into action. Our evidence suggests this second behavior is more likely the explanation.

[Table 3](#) splits the panel of countries at the median of their 2008 level of democracy—measured by V-Dem’s Electoral Democracy Index ([Coppedge et al. 2024](#))—and interacts the post-scandal indicator with the resulting above-/below-median classification. The violent-protest response is positive in both groups but, if anything, larger and more persistent in the *above*-median (higher-democracy) countries: the ± 30 -day effect is 0.021 ($p < 0.05$) in higher-democracy countries versus 0.009 ($p < 0.1$) in lower-democracy ones, and the gap persists at the wider windows. However, we cannot statistically distinguish the two (the ± 30 -day violent-count difference has $p = 0.245$), so this heterogeneity is suggestive rather than conclusive.

[Table 4](#) sharpens the comparison by grouping countries into terciles of the 2008 Electoral Democracy Index and pooling the top two (“Medium+High”) against the bottom tercile (“Low”). The violent-protest

Table 2. Violent protests increase after apex corruption scandal disclosures.

OLS estimates of β from Equation 1. Columns are violent and peaceful protest counts at four event-window widths: ± 30 days (cols. 1–2), ± 60 (cols. 3–4), ± 90 (cols. 5–6) and ± 120 (cols. 7–8). Panel A: Apex scandals (President, Governors and Supreme Court Justices; 63 scandals). Panel B: Non-Apex scandals (Congressmen, lower judiciary, and other officials; 113 scandals). Panel C: national-team football match losses. Panel D: currency depreciation episodes (a month-on-month depreciation of the exchange rate of more than 5%). An observation is a country-day inside the event window of the corresponding event. All specifications include country-by-year, month-of-year, and day-of-week fixed effects; standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. “Mean (Pre-Event)” is the average outcome over the same $\pm$ window as the column (the 30 days before the event for the ± 30 columns, the 60 days before for the ± 60 columns, and so on). Sample period 2008–2018; Venezuela excluded. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

effect is larger in the Medium+High group at every window and the one-sided ordering $\beta_{\text{Medium+High}} > \beta_{\text{Low}}$ strengthens at the wider windows—so, to the extent the heterogeneity is real, it is the *higher*-democracy countries that drive the effect.

4 Discussion

The evidence we have presented suggests citizens do not respond uniformly to all types of corruption: they respond sharply, immediately and durably when the implicated official is at the apex of the political spectrum, and they barely respond when the implicated official sits at the lower tier of the

OLS estimates of $\beta_{\text{Medium+High}}$ and β_{Low} , the post-scandal indicator interacted with a top-two-tercile (“Medium+High”) and a bottom-tercile (“Low”) flag from terciles of V-Dem’s 2008 Electoral Democracy Index (`v2x_polyarchy`). Columns are violent and peaceful protest counts at the $\pm 30/60/90$ -day windows. “p-value: Medium+High = Low” reports the two-sided p -value for $H_0 : \beta_{\text{Medium+High}} = \beta_{\text{Low}}$; “p-value: Medium+High > Low (one-sided)” reports the one-sided p -value. Same fixed effects, clustering, and sample as Table 2. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

hierarchy. Furthermore, the response concentrates on violent protests and persists even in a four month window. The peaceful margin stays essentially flat over both horizons and regardless of whether the scandal implicates an Apex or Non-Apex politician. Our findings underscore the fact that corruption is a tangible behavioral shock to the local (and perhaps even regional) political environment, not just an attitudinal one. The stakes citizens hold in the continuation in office of a corrupt official appear to govern whether citizens mobilize, and how they do so. The joint pattern—a persistent rise in violent protests with no corresponding change on the peaceful margin—is consistent with, though our design does not establish, citizens turning to violent rather than peaceful channels when a scandal undercuts

their confidence in the officials meant to be held accountable.

Our findings contribute to three literatures. First, the economics-of-conflict literature has documented that political violence responds to economic shocks (König et al. 2017; McGuirk and Burke 2020; Dube and Vargas 2013; Besley and Persson 2011; Berman et al. 2011; Rohner et al. 2026). We introduce a *political* shock—public disclosure of apex corruption—and show that it produces mobilization responses of comparable magnitude to the ones caused by economic shocks. Second, the corruption and accountability literature has documented that disclosures of malfeasance change voting behavior (Ferraz and Finan 2008, 2011a,b; Avis et al. 2018; Arias et al. 2019). The slow electoral horizon has tended to obscure that the same disclosures can have very fast, non-electoral consequences (Madestam et al. 2013; Bursztyn et al. 2021). Our high-frequency design uncovers a channel through which apex corruption shapes the political environment in democracies within days of public disclosures, well before subsequent elections come into play. Third, the protest channel is the behavioral complement of the attitudinal evidence from our companion paper (Rivera et al. 2024), which documents that apex corruption scandals erode support for democracy and democratic institutions, and also reduce political participation.

Our results help reconcile part of the mixed results in the existing literature on the political consequences of corruption disclosures. Studies of local level corruption have produced muted estimates of disclosure’s electoral consequences, with some finding modest accountability gains in Brazil and Spain (Ferraz and Finan 2008, 2011a; Avis et al. 2018; Costas-Pérez et al. 2012) and others finding null or even demobilizing effects (Chong et al. 2015; Anduiza et al. 2013; Pavão 2018; Arias et al. 2022). We argue that the dispersion in municipal estimates reflects the limited political stakes at that level. In particular, when the implicated official is one of many municipal officeholders, citizens have weaker incentives to incur the costs of mobilization. Within our sample, scandals implicating Congressmen, lower judiciary and lower rank officials have *immediate* (30-day) post-scandal effects on violent protests statistically indistinguishable from zero, whereas the effect of scandals implicating a President or Other Apex official is large and immediate.

A “salience of stakeholders” view rationalizes this (Acemoglu and Robinson 2006, 2012; Jha 2013; Jha and Shayo 2019; Jha 2022). Citizens’ political behavior responds to the political weight of *what* is being disclosed. Apex corruption, thus, affects citizens’ perceived stakes of the political bargain, particularly when the implicated official is at the apex of the political hierarchy. The contrast between high-stakes apex scandals and low-stakes lower-officials scandals parallels the contrast between high-stakes elections and routine governance in studies of political accountability (Martinez-Bravo et al. 2022). Notably, this response does not require weak institutions to appear: it is present across our sample and,

if anything, somewhat stronger in the more democratic countries, where citizens plausibly hold higher expectations of accountability—and enjoy greater latitude to voice them—when those expectations are violated (Acemoglu et al. 2019, 2024; Depetris-Chauvin et al. 2020).

Our empirical analyses have some limitations worth noting. Our identification strategy relies on the timing of apex corruption disclosures, not on the timing of the corrupt act itself. If the timing of disclosures is correlated with pre-existing political conditions that affect mobilization (violent or peaceful), our estimates could then be biased. Somewhat reassuringly, the pre-scandal estimates in Figure 1 show no evidence of pre-existing trends in mobilization. A second limitation comes from the fact that the MM dataset is constructed by looking at news sources reporting on mobilization events. Small protests may thus be underreported as they are not big enough to draw media attention, or protests occurring in geographically remote areas may also be left out. This would induce measurement error in our estimates, but if anything this would bias our estimates toward zero. And finally, our scandal sample is limited to Latin American democracies in the 2008–2018 period, thus limiting the external validity of our findings insofar as different regions in the world may mobilize differently in response to corruption scandals. One could also expect different results when shortening/expanding the time scope of the analysis if one believes that the cumulative amount of apex corruption episodes affect the extent to which citizens mobilize.

Supplementary Materials

S1 Scandal classification

Each of the 176 scandals in our event-window panel is manually classified by the position of the implicated politician, in two steps. *Step 1 (raw position)*. Starting from the free-text description of each scandal, a research assistant assigns one of five raw codes: **president** (sitting or immediately-former head of state); **governor** (head of a first-order subnational unit); **sc_judge_congressman** (a Supreme Court Justice *or* a national legislator); **other_judiciary** (lower-court judges, prosecutors); and **others** (ministers, agency heads, mayors, and all remaining officials). *Step 2 (splitting sc_judge_congressman)*. Because that raw code lumps constitutional-court justices together with members of Congress, we verify each such row and tag the ones implicating a Supreme Court justice; the re-tagged IDs are 202, NEW26, NEW30, and 332. We then aggregate into three bins: **President** = president (45 scandals); **Other Apex** = governor plus the four SC-Justice IDs (18 scandals); and **Non-Apex** = other_judiciary + others + the remaining sc_judge_congressman IDs (Congressmen; 113 scandals). Throughout the paper “Apex” pools the President and Other Apex bins (63 scandals).

[Table S1](#) lists every scandal in the panel with its scandal ID, country, year, a short description, and its Apex/Non-Apex classification. The scandal ID is the identifier used to disambiguate the leave-one-out labels in [Appendix S8](#) when a country has more than one scandal in the same year within a group. One earlier borderline case, ID NEW23 (Mexico, 2017), was originally re-tagged as a Supreme Court justice but its source describes a San Luis Potosí case implicating *diputados* (members of Congress); we therefore classify it as Non-Apex. Four scandals had blank descriptions in the classification file; we recovered them from the underlying news source and report them in the table.

Table S1. Classification of the 176 scandals in the event-window panel.

S2 Randomization inference by apex-partition subsample

We complement the headline estimates with a randomization-inference (permutation) test, run separately on the two subsamples of Table 2. In each of 1,000 replications and for each scandal we draw a placebo disclosure date uniformly at random within the scandal’s original country-year, rejecting any draw whose $\pm T$ -day window would overlap a real disclosure date in the same country-year (with an unconditional fallback over all countries and 2008–2018 dates after 20 failed within-country-year attempts). We rebuild the $\pm T$ -day event-window panel around the accepted placebo dates and re-estimate the headline OLS specification. Figures S1 and S2 plot the resulting placebo $\hat{\beta}$ distributions; the maroon vertical line marks the observed $\hat{\beta}$ from the corresponding cell of Table 2, and the legend reports that observed $\hat{\beta}$ together with the two-sided randomization-inference p -value. For violent protests the observed effect sits in the upper tail—most sharply for the Apex subsample—while for the Non-Apex subsample and for peaceful protests it lies within the placebo mass.

Figure S1. Randomization inference: violent protests.

Randomization inference for violent protests. Each histogram is the distribution of 1,000 placebo estimates of the post-scandal effect, obtained by redrawing each scandal’s disclosure date at random within its own country-year and re-estimating Equation 1 on the $\pm T$ event window. Top row: Apex subsample; bottom row: Non-Apex; columns are the ± 30 , ± 60 , and ± 90 day windows. The maroon vertical line (drawn on top) marks the observed $\hat{\beta}$ from the corresponding cell of Table 2; the top-right legend reports that observed $\hat{\beta}$ and the two-sided randomization-inference p -value. Standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.

Figure S2. Randomization inference: peaceful protests.

Randomization inference for peaceful protests. Each histogram is the distribution of 1,000 placebo estimates of the post-scandal effect, obtained by redrawing each scandal's disclosure date at random within its own country-year and re-estimating Equation 1 on the $\pm T$ event window. Top row: Apex subsample; bottom row: Non-Apex; columns are the ± 30 , ± 60 , and ± 90 day windows. The maroon vertical line (drawn on top) marks the observed $\hat{\beta}$ from the corresponding cell of Table 2; the top-right legend reports that observed $\hat{\beta}$ and the two-sided randomization-inference p -value. Standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.

S3 Sensitivity to the event-window width

We re-estimate the headline OLS specification at every event-window width $T \in \{15, 30, 45, \dots, 150\}$ days and plot the point estimate against T with a 90% confidence interval. Figure S3 places the Apex and Non-Apex subsamples *side by side*—violent protests in the top row, peaceful in the bottom—on a *common y-axis across all four panels*, so the Apex and Non-Apex responses can be compared directly by eye. The four widths reported in Table 2 ($T = 30, 60, 90, 120$) are highlighted in red; the effect on violent protests in the Apex subsample is positive across the full range of windows, while the Non-Apex response stays close to zero.

Figure S3. Window-width sensitivity: Apex vs. Non-Apex.

For each $T \in \{15, 30, \dots, 150\}$ we re-estimate the headline OLS specification on the event-window panel restricted to $|w_{st}| \leq T$, separately on the 63 Apex and 113 Non-Apex scandals. Vertical bars are 90% confidence intervals; the markers at $T = 30, 60, 90, 120$ (the widths in Table 2) are highlighted in red. All four panels share a common y-axis so Apex and Non-Apex are directly comparable. Sample period 2008–2018; Venezuela excluded.

S4 Event studies by subsample (15-day bins)

Figure 1 in the main text reports the subsample event study—estimated separately on the Apex and Non-Apex samples—at the ± 60 -day window. This section reports the same specification at the ± 30 and ± 90 -day windows, keeping 15-day bins throughout. Within each figure all four panels—violent and peaceful, Apex and Non-Apex—share a common y-axis range, so the estimates can be compared by eye and the zero line is aligned across panels.

Figure S4. Event studies, ± 30 -day window (15-day bins).

OLS event study estimated separately on the Apex and Non-Apex subsamples, on 15-day event-time bin indicators over the ± 30 -day window (Equation 1 with the post indicator replaced by a saturated set of event-time bins). The four panels are violent and peaceful protests $\times$ Apex and Non-Apex; the reference bin (the 15 days before disclosure) is normalized to zero and shown at its position, and the faint thick vertical line marks the disclosure cutoff. All four panels share a common y-axis. Vertical bars are 90% confidence intervals; standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.

Figure S5. Event studies, ± 90 -day window (15-day bins).

OLS event study estimated separately on the Apex and Non-Apex subsamples, on 15-day event-time bin indicators over the ± 90 -day window. The four panels are violent and peaceful protests $\times$ Apex and Non-Apex; the reference bin (the 15 days before disclosure) is normalized to zero and shown at its position, and the faint thick vertical line marks the disclosure cutoff. All four panels share a common y-axis. Vertical bars are 90% confidence intervals; standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.

S5 Regression-based hierarchy analysis

Table S2 reports the pooled-regression analogue of the apex partition, splitting the interaction into all three bins. For each outcome and window we estimate

$$Y_{c(s)t} = \beta_{\text{Pres}} \text{Post}_{st} \mathbf{1}\{\text{Pres}_s\} + \beta_{\text{OA}} \text{Post}_{st} \mathbf{1}\{\text{OA}_s\} + \beta_{\text{ONA}} \text{Post}_{st} \mathbf{1}\{\text{ONA}_s\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t},$$

where Pres_s , OA_s , ONA_s are scandal-level indicators for President, Other Apex, and Non-Apex. The specification omits a stand-alone Post term, so each coefficient is the average post-scandal effect for that category, and we report the p -values from pairwise equality tests.

Table S2. Pooled interaction regression: hierarchy of the protest response.

	± 30 -Day Window		Shares (± 30 -Day)	
	(1) Violent Protests	(2) Peaceful Protests	(3) Share Violent	(4) Share Peaceful
Post $\times$ President	0.028*** (0.009)	-0.001 (0.009)	0.027*** (0.009)	-0.001 (0.008)
Post $\times$ Other Apex	0.112** (0.047)	-0.021 (0.031)	0.113** (0.047)	-0.015 (0.028)
Post $\times$ Other Non-Apex	-0.004 (0.007)	0.019 (0.013)	-0.005 (0.007)	0.019 (0.013)
p-value: President = Other Non-Apex	0.006	0.237	0.005	0.215
p-value: Other Apex = Other Non-Apex	0.028	0.303	0.025	0.336
p-value: President = Other Apex	0.066	0.478	0.058	0.570
Mean (Pre-Scandal Bin)	0.027	0.069	0.027	0.061
Observations	10736	10736	10736	10736
Number of Scandals	176	176	176	176
R-squared	0.178	0.474	0.186	0.494

OLS estimates of β_{Pres} , β_{OA} , β_{ONA} (Post $\times$ President, Other Apex, Non-Apex) on the four count outcomes (cols. 1–4) and four share outcomes (cols. 5–8). Standard errors (in parentheses) clustered at the country $\times$ year $\times$ day-bin level. Fixed effects, sample period, and clustering identical to Table 2. Rows labeled “ p -value” report pairwise equality tests across the three category coefficients.

S6 Democracy: alternative indices and country classification

Table S3 lists the sample countries (sorted by their 2008 V-Dem Electoral Democracy Index) and shows how each is classified—High, Medium, or Low—under four different 2008 democracy measures, so the tercile grouping used throughout is not an artefact of a single index. Table S4 then re-estimates the electoral-democracy split (Table 4 in the main text) using an alternative continuous index, V-Dem’s Liberal Democracy Index, in place of the Electoral index, and Table S5 reports the corresponding Low vs. Medium+High pooled split—the liberal-index analogue of Table 4. Finally, Table S6 repeats the by-level split using Freedom House’s 2008 status (Free vs. Partly Free). The ordering of the effects is preserved throughout.

Table S3. Country democracy classification across four indices.

Country	V-Dem Electoral	V-Dem Liberal	Polity2	Freedom House
Costa Rica	High	High	High	High
Chile	High	High	High	High
Brazil	High	High	Low	High
Peru	High	High	High	High
Argentina	High	High	Low	High
Panama	Medium	Medium	High	High
Bolivia	Medium	Medium	Low	Medium
Mexico	Medium	Medium	Low	High
Dominican Republic	Medium	Low	Low	High
Ecuador	Medium	Low	Low	Medium
Paraguay	Low	Medium	Low	Medium
Guatemala	Low	Low	Low	Medium
Colombia	Low	Medium	Low	Medium
El Salvador	Low	Low	Low	High
Honduras	Low	Low	Low	Medium
Nicaragua	Low	Low	High	Medium

Each country’s High / Medium / Low classification under four 2008 democracy measures: V-Dem Electoral Democracy (v2x_polyarchy), V-Dem Liberal Democracy (v2x_libdem), Polity2 (e_polity2), and Freedom House status (e_fh_status; Free / Partly Free / Not Free mapped to High / Medium / Low). For the three continuous indices the classification is the country’s tercile; Polity2 discriminates poorly among these consolidated democracies (its scores cluster near the top), so its tercile split is noisier than the V-Dem indices. Countries are sorted by the V-Dem Electoral index.

Table S4. Effect by 2008 level of democracy, tercile split: V-Dem Liberal Democracy Index.

	± 30 -Day Window		± 60 -Day Window		± 90 -Day Window	
	(1) Violent Protests	(2) Peaceful Protests	(3) Violent Protests	(4) Peaceful Protests	(5) Violent Protests	(6) Peaceful Protests

p-value: Medium > Low (one-sided)	0.095	0.053	0.257	0.222	0.259	0.229
p-value: High > Low (one-sided)	0.432	0.157	0.102	0.258	0.141	0.410
Mean (Pre-Scandal)	0.020	0.053	0.021	0.056	0.024	0.057
Observations	10736	10736	21296	21296	31856	31856
Number of Scandals	176	176	176	176	176	176
R-squared	0.160	0.473	0.154	0.396	0.133	0.348

The electoral-index tercile split, but with terciles formed from V-Dem's 2008 *Liberal Democracy Index* (v2x_1libdem) rather than the Electoral index. OLS estimates of β_{High} , β_{Medium} , and β_{Low} (the post-scandal indicator interacted with top-, middle-, and bottom-tercile flags), on violent and peaceful protest counts at the $\pm 30/60/90$ -day windows. The rows report the one-sided p -values for the orderings High > Medium, Medium > Low, and High > Low. All specifications include country-by-year, month-of-year, and day-of-week fixed effects; standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. Sample period 2008–2018; Venezuela excluded. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

Table S5. Effect by 2008 level of democracy (Liberal index): Low vs. Medium+High.

	± 30 -Day Window		± 60 -Day Window		± 90 -Day Window	
	(1) Violent Protests	(2) Peaceful Protests	(3) Violent Protests	(4) Peaceful Protests	(5) Violent Protests	(6) Peaceful Protests
Post $\times$ Medium+High Democracy (Liberal, 2008)	0.019*** (0.007)	0.017** (0.008)	0.021*** (0.008)	0.006 (0.009)	0.016** (0.007)	0.000 (0.008)
Post $\times$ Low Democracy (Liberal, 2008)	0.009* (0.006)	-0.007 (0.016)	0.010 (0.006)	-0.011 (0.021)	0.004 (0.009)	-0.009 (0.016)
p-value: Medium+High = Low	0.257	0.166	0.269	0.450	0.312	0.593
p-value: Medium+High > Low (one-sided)	0.128	0.083	0.134	0.225	0.156	0.296
Mean (Pre-Scandal)	0.020	0.053	0.021	0.056	0.024	0.057
Observations	10736	10736	21296	21296	31856	31856

R-squared	0.160	0.473	0.154	0.396	0.133	0.348

The by-democracy-level split using Freedom House's 2008 status (`e_fh_status`) instead of a V-Dem index. Freedom House classifies each country as Free, Partly Free, or Not Free; among the 16 sample countries none is Not Free, so this is a Free (9 countries) vs. Partly Free (7 countries) comparison. OLS estimates of β_{Free} and $\beta_{\text{Partly Free}}$ (the post-scandal indicator interacted with a Free and a Partly-Free flag), on violent and peaceful protest counts at the $\pm 30/60/90/120$ -day windows. “p-value: Free = Partly Free” reports the two-sided p -value for $H_0 : \beta_{\text{Free}} = \beta_{\text{Partly Free}}$; “p-value: Free > Partly Free (one-sided)” reports the one-sided p -value for $H_1 : \beta_{\text{Free}} > \beta_{\text{Partly Free}}$. All specifications include country-by-year, month-of-year, and day-of-week fixed effects; standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. Sample period 2008–2018; Venezuela excluded. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

S7 Regression discontinuity in event time

An alternative to the event-study and difference-in-differences designs treats the scandal disclosure as a *regression discontinuity in time*: the running variable is the number of days since the scandal ($w_{s,t}$), the cutoff is the disclosure date ($w_{s,t} = 0$), and treatment is $\text{Post}_{st} = \mathbf{1}\{w_{s,t} \geq 0\}$. A polynomial in the running variable, allowed to differ on each side of the cutoff, models the smooth pre- and post-scandal trend; the discontinuity at 0 is the immediate effect of disclosure, net of that trend. This handles the incoming pre-scandal trend transparently and needs none of the staggered-DiD machinery.

Table S7 reports the estimated jump for the apex and non-apex subsamples, on violent and peaceful protests, for bandwidths $h \in \{30, 60, 90\}$ days and local-linear and local-quadratic polynomials. The local-linear estimate—the standard, and preferred over higher-order polynomials—shows a clear positive discontinuity in violent protests for apex scandals (0.034 at $h = 30$, 0.067 at $h = 60$) and no discontinuity for non-apex scandals or on the peaceful margin. Figure S6 plots the two violent-protest discontinuities: for apex scandals the residualised protest count jumps sharply upward at disclosure, whereas for non-apex scandals the fit is continuous through the cutoff. Reassuringly, the apex pre-scandal trend is, if anything, *downward*, so the upward jump is not an artefact of a rising pre-trend.

Table S7. Regression discontinuity in event time: jump at disclosure.

	Violent Protests			Peaceful Protests		
	$h = 30$	$h = 60$	$h = 90$	$h = 30$	$h = 60$	$h = 90$
<i>Apex</i>						
Local linear	0.034 (0.022)	0.066*** (0.018)	0.056*** (0.016)	0.008 (0.018)	0.008 (0.016)	0.000 (0.014)
Local quadratic	0.038 (0.032)	0.024 (0.024)	0.067*** (0.024)	0.009 (0.022)	0.000 (0.022)	0.012 (0.021)
Nonparametric	0.029 (0.031)	0.031 (0.029)	0.030 (0.029)	-0.002 (0.021)	0.004 (0.021)	0.006 (0.021)
<i>Non-Apex</i>						
Local linear	0.004 (0.014)	-0.005 (0.008)	-0.001 (0.010)	-0.012 (0.022)	0.010 (0.020)	0.007 (0.021)
Local quadratic	0.013 (0.020)	0.006 (0.016)	-0.005 (0.014)	-0.013 (0.025)	-0.011 (0.031)	0.003 (0.031)
Nonparametric	0.012 (0.016)	0.008 (0.017)	0.007 (0.018)	-0.010 (0.023)	-0.013 (0.030)	-0.012 (0.033)

Estimated discontinuity (τ , standard error in parentheses) in the daily protest count at the disclosure cutoff ($w_{s,t} = 0$), from $Y_{c(s)t} = \tau \text{Post}_{st} + f(w_{s,t}) + \text{Post}_{st} \cdot g(w_{s,t}) + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t}$, where the polynomials f, g are local-linear or local-quadratic in the running variable and, the running variable being centred at 0, the coefficient on Post is exactly the jump at the cutoff. The “Nonparametric” rows instead report a local-polynomial estimate (rdrobust: MSE-optimal data-driven bandwidth, triangular kernel) computed within the $\pm h$ window on the fixed-effect-residualised outcome. Estimated separately on the apex and non-apex subsamples, on violent and peaceful protest counts, at bandwidths/windows $h \in \{30, 60, 90\}$ days. All specifications include country-by-year, month-of-year, and day-of-week fixed effects; standard errors clustered at the country $\times$ year $\times$ day-bin level. Sample period 2008–2018; Venezuela excluded. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

The result is robust to the polynomial choice—the local-quadratic estimates are in Table S7, and

Figure S7 plots the corresponding local-quadratic fits, which likewise jump upward at disclosure for apex scandals only—and to a fully non-parametric fit: the “Nonparametric” rows of Table S7 report a local-polynomial regression-discontinuity estimate (Calonico et al. 2014), computed within each window with an MSE-optimal, data-driven bandwidth and a triangular kernel on the fixed-effect-residualised outcome, and Figure S8 shows the corresponding local-linear fits with 90% confidence bands. The apex violent discontinuity is positive at every window; with the wider robust confidence bands it is not always individually significant, while the non-apex and peaceful estimates remain null throughout.

Figure S6. Regression discontinuity in event time, violent protests, at $h = 30/60/90$ -day bandwidths.

Binned means of the violent-protest count—residualised on the country-by-year, month-of-year, and day-of-week fixed effects—in 5-day bins of the running variable (days since scandal), with local-linear fits on each side of the disclosure cutoff, at the $h = 30$ (top row), $h = 60$ (middle), and $h = 90$ (bottom) bandwidths. For apex scandals (left column) the count jumps upward at $w_{s,t} = 0$ at every bandwidth; for non-apex scandals (right column) the fit is continuous through the cutoff. All regression-discontinuity figures share a common vertical scale so the discontinuities can be compared by eye. Sample period 2008–2018; Venezuela excluded.

Figure S7. Regression discontinuity in event time, local-quadratic fit, violent protests, at $h = 30/60/90$ -day bandwidths.

As Figure S6, but with local-quadratic fits on each side of the disclosure cutoff, at the $h = 30$ (top row), $h = 60$ (middle), and $h = 90$ (bottom) bandwidths. Binned means of the violent-protest count, residualised on the country-by-year, month-of-year, and day-of-week fixed effects, in 5-day bins of the running variable. For apex scandals (left column) the count jumps upward at $w_{s,t} = 0$; for non-apex scandals (right column) the fit is continuous through the cutoff. Common vertical scale across all regression-discontinuity figures. Sample period 2008–2018; Venezuela excluded.

Figure S8. Regression discontinuity in event time, non-parametric fit, violent protests, at $\pm 30/60/90$ -day windows.

Local-linear fits (triangular kernel, MSE-optimal data-driven bandwidth) with 90% confidence bands, and binned means (12 per side), of the violent-protest count residualised on the country-by-year, month-of-year, and day-of-week fixed effects, on each side of the disclosure cutoff. Each row restricts estimation to a ± 30 (top), ± 60 (middle), or ± 90 (bottom) day window, within which `rdrobust` selects its own MSE-optimal bandwidth; the legend reports the resulting discontinuity estimate τ and its p -value. Apex scandals in the left column, non-apex in the right. Common vertical scale across all regression-discontinuity figures. Sample period 2008–2018; Venezuela excluded.

S8 Leave-one-out robustness by scandal

We re-estimate the two interaction coefficients on violent protests in the ± 30 -day window, dropping one scandal's event window at a time, split by scandal type (Apex vs. Non-Apex, [Figure S9](#)). No single scandal drives its coefficient—the leave-one-out estimates cluster tightly on the full-sample line (red). For the apex effect, removing the single most influential scandal lowers β_{Apex} from about 0.048 to 0.029 but leaves it clearly positive. The two panels share a common vertical axis so the magnitudes are directly comparable.

Figure S9. Leave-one-out by scandal type.

(a) Apex: β_{Apex} (Post $\times$ Apex), dropping each apex scandal.

(b) Non-Apex: $\beta_{\text{Non-Apex}}$ (Post $\times$ Non-Apex), dropping each non-apex scandal.

Leave-one-out estimates of the two-group interaction coefficients (??) on violent protests, ± 30 -day window. Each point re-estimates the panel's coefficient—Post $\times$ Apex in (a), Post $\times$ Non-Apex in (b)—dropping the labelled scandal's event window; panel (a) leaves out each of the 63 apex scandals, panel (b) each of the 113 non-apex scandals. Vertical bars are 90% confidence intervals; scandals (x-axis, Country – Year) are sorted by the estimate. The red line is the coefficient on all scandals and the faint line marks zero; the two panels share a common vertical scale. Standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.
