

Apex Corruption causes Violent Protests*

Roberto González-Téllez[†] Saumitra Jha[‡] Eduardo Rivera[§] Enrique Seira[¶]

This draft: 2026-07-14

Abstract

We document that *apex* corruption scandals—corrupt acts implicating top-level politicians—cause immediate and persistent increases in violent protests. Using a panel of 176 corruption scandals across 23 countries in Latin America from 2008 to 2018, merged with daily protest counts, we establish three facts: In the 30 days following a scandal, the daily count of violent protests rises by roughly 59% of the pre-scandal baseline (measured over the six days immediately preceding disclosure). The effect appears within a week of the scandal, and remains positive even four months later. The magnitude of the effect scales sharply with the political rank of the implicated agent: the per-scandal median effect for sitting presidents is substantially larger—about an order of magnitude, though based on a small number of informative scandals—than the corresponding median for Governors or Supreme Court judges. Our findings identify a high-frequency, high-magnitude channel through which corruption shapes the political environment in democracies.

*We thank seminar audiences and colleagues for helpful comments. All errors are our own.

1 Introduction

Political violence is among the most consequential outcomes a democracy can experience. Civil unrest disrupts economic activity, displaces investment, and—when met with state violence in return—erodes the social contract that legitimizes the regime. An influential economic literature has linked political violence to economic shocks (Miguel et al. 2004; McGuirk and Burke 2020), to commodity rents and network structure (König et al. 2017; Dube and Vargas 2013), to the foundations of state capacity (Besley and Persson 2011), and in recent work to abrupt withdrawals of foreign assistance (Rohner et al. 2026). Related work shows that protests themselves can produce durable political effects (Madestam et al. 2013; Bursztyn et al. 2021). The contribution of political shocks to events that change citizens’ beliefs about who governs them, however, has received considerably less attention. In this paper we argue that disclosures of apex corruption are one such shock, and that the behavioral consequences for political violence are large, immediate, and persistent.

Corruption has been long studied, with known costs for growth and public goods provision (Mauro 1995; Treisman 2007; Olken 2007; Olken and Pande 2012; Glaeser and Saks 2006). In the past two decades, citizens’ perceptions of corruption prevalence have risen (Cantoni et al. 2024), and corruption scandals associated to *apex* politicians have drawn more attention from news outlets in recent years (Rivera et al. 2024); perhaps unsurprisingly due to the expansion of social media, which reduces the cost of diffusing information and enables news outlets to reach broader audiences (Enikolopov et al. 2018; Tufekci 2024; DellaVigna and Kaplan 2007). Even though exposing corruption scandals on news outlets can have positive desired effects, such as political accountability or crackdowns of corruption networks (Ferraz and Finan 2011a; Arias et al. 2019, 2022), it can also have negative undesired effects on democratic values (Ajzenman 2021; Rivera et al. 2024) and away from the polling booths. Public exposure of malfeasance by sitting officials changes what citizens believe about who governs them and about the rules under which the government operates. The most consequential corruption-related political moments of the last decade, such as Brazil’s Lava Jato¹, were mobilization events, not electoral ones.

We document that apex corruption—corrupt acts implicating top-level politicians—triggers immediate and persistent increases in violent protests across Latin American democracies. Using a hand-curated panel of 176 corruption scandals across 23 countries from 2008 to 2018, merged with daily protest counts from the Mass Mobilization (MM) project (Clark and Regan 2016), we establish three facts. First, the daily count of violent protests rises by about 59% of the pre-scandal baseline (the mean of the outcome in the six days immediately preceding disclosure) over the 30 days following the

¹See [this video](#) for more information on the scandal.

scandal. The count of peaceful protests, in the same 30-day window, remains largely unaffected. Second, the effect appears within a week of the scandal disclosure, and the point estimate remains positive even four months later. Third, the magnitude of the effect scales with the political rank of the implicated agent: the per-scandal median effect for sitting presidents is substantially larger—about an order of magnitude, though based on a small number of informative scandals—than the corresponding median for Governors or Supreme Court judges. Scandals involving Congressmen, lower judiciary, and other non-apex officials leave protest patterns broadly unchanged.

2 Method

2.1 Study Design and Measures

Our empirical analyses exploit the randomness of corruption scandal disclosures in Latin American news outlets between 2008 and 2018. In particular, we use an interrupted time-series design in which we compare protest occurrences in countries with scandals before and after the scandal occurs. Our analysis dataset is created by: (i) Scraping the Twitter accounts from news outlets in Latin America to identify the calendar date in which a scandal in a given country is first reported², (ii) create an event-window of $T \in \{30, 120\}$ days before and after the scandal, (iii) merge the country-day count of protests from the MM data to create a ‘scandal-protest’ dataset for a given country in a given calendar-date window, and lastly, (iv) append all such scandal-protest datasets to build the analysis dataset.

The MM dataset is available for the period 1990–2020, and it includes information on the date, size, and location of any episode in which 50 or more protesters publicly demonstrate against the State. If a protest lasts X days, we code the occurrence of a protest at date $t, t+1, \dots, t+X-1$. If the same protest is associated with more than one date (e.g., because the news source for the protest cannot accurately identify whether it is a continued or a new protest), then we keep the date of the earliest protest. For a protest to be classified as “violent”, “[t]he violence could include anything from riotous behavior that destroys property to shooting at the police or military” (Clark and Regan 2016). Our main outcome is the number of protests occurring in a given country-date. We focus on the years 2008–2018, given that our corruption scandals data is available for those years.

We use Ordinary Least Squares (OLS)—and Poisson Quasi-maximum Likelihood Estimation (QML) to account for the count nature of the outcome—to estimate the following equation:

$$Y_{c(s)t} = \beta \mathbb{1}\{t \geq \text{Scandal Date}_{c(s)}\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t} \quad (1)$$

²We keep the date of the first news report to (a) be able to estimate the effect of a scoop, and (b) avoid double-counting a scandal due to follow-up news reports on it.

where α_d denote day of the week fixed effects, λ_m denote month of the year fixed effects, θ_{cy} denote country-year fixed effects, $\text{Scandal Date}_{c(s)}$ is the date in which corruption scandal s in country c occurs, Y_{ct} denotes the outcome of interest in country c at date t , and $\varepsilon_{c(s)t}$ is an idiosyncratic error term.

To trace dynamics we replace $\mathbb{1}\{t \geq \text{Scandal Date}_{c(s)}\}$ in Equation 1 with a saturated set of 30-day bin indicators for four months before/after the scandal. The reference category in each time-to-event graph is the bin immediately before disclosure (i.e., $w_{s,t} \in [-30, -1]$).

The identification assumption we rely on for our estimates to be interpreted as causal is that conditional on country-year, month-of-year, and day-of-week fixed effects, the within-year date of disclosure of a scandal is as-good-as-randomly assigned in relation to the protest baseline of the country. The country-year fixed effects absorb every source of country-year-level confounding such as pre-existing political instability, electoral calendars, or institutional reforms. The day-of-week and month-of-year fixed effects absorb weekly and seasonal cycles in protest activity.

3 Results

3.1 Apex corruption increases violent protests

Table 1 reports our OLS (Panel A) and Poisson (Panel B) estimates of the effect of apex corruption on violent and peaceful protests in 30- and 120-day windows. In our OLS specification, we estimate an increase of 0.016 violent protests per country-day in both the one and four months windows ($P < 0.01$ and $P = 0.012$, respectively), roughly 59% of the pre-scandal mean in the week before the scandal. Peaceful protests do not show statistically nor economically significant effects. In the 30-day window, we estimate an increase of 0.01 protests per country-day ($P = 0.219$, 14% of the pre-scandal-bin mean), and a 0.009 *decrease* in the 120-day window ($P = 0.212$, 17% of the pre-scandal-bin mean). The Poisson QML estimates—which account for the count nature of the outcome—imply large proportional effects: violent protests rise by 54% in the 30-day window ($P < 0.001$) and by 63% in the 120-day window ($P = 0.047$). Peaceful protests, on the other hand, show effects in opposing directions on the two time windows: they increase by 25% in the 30-day window following the scandal ($P = 0.095$), and they *decrease* by 21% in the 120-day window after the scandal disclosure ($P = 0.049$). The opposite-signed peaceful-protest point estimates across windows are suggestive of, but do not identify, a shift from peaceful to violent mobilization on the longer horizon: our design compares within-country pre- and post-scandal outcomes and cannot separate a substitution mechanism from an independent decline in peaceful protests over the four-month horizon.

The table reports OLS estimates of β from Equation 1, split by the political rank of the implicated official. Panel A restricts the sample to scandals implicating a sitting President or an Other Apex official (Governors and Supreme Court Justices; 64 scandals total). Panel B restricts to Other Non-Apex scandals (Congressmen, lower judiciary, and other officials; 112 scandals). Each panel reports eight outcome–window combinations: violent and peaceful protest *counts*, each estimated on the ± 30 -day window (columns 1–2) and on the ± 120 -day window (columns 3–4); and *share* outcomes, defined as the fraction of the country-day’s protests that are violent or peaceful (with country-days having no protests imputed to a share of 0), estimated on the ± 30 -day window (columns 5–6) and on the ± 120 -day window (columns 7–8). An observation is a country-day inside the event window of a scandal in the corresponding subsample. All specifications include country-by-year, month-of-year, and day-of-week fixed effects. Standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. “Mean (Pre-Scandal Bin)” is the average value of the outcome in the bin immediately before the scandal’s disclosure—a 6-day bin in columns (1)–(2) and (5)–(6) and a 30-day bin in columns (3)–(4) and (7)–(8)—computed over the corresponding regression sample. The sample period is 2008–2018; Venezuela is excluded. The corresponding Poisson QML incidence-rate ratios are reported in Table S1. Significance: * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

3.2 Protest dynamics around apex corruption scandals

In Figure 1 we show OLS estimates of the dynamics of the effects of apex corruption scandals using our modified Equation 1, in which we substitute the indicator for post-scandal dates with a fully saturated set of indicators for 30-day bins of dates (in the 120-day window) within the scandal date.

Violent protests (Figure 1a) show no trend prior to the scandal disclosures, and then suddenly increase by 0.014 protests per country-day in the first 30-days after the scandal disclosure, relative to the 30-days before the scandal disclosure ($P = 0.110$). The point estimates remain positive and similar in magnitude in the three months that follow. Peaceful protests (Figure 1b) follow a different trajectory. Prior to the scandal there is no statistically significant trend, and they do not exhibit changes after scandal disclosure, with point estimates ranging from -0.007 to 0.004 ($P = 0.513$ and $P = 0.745$, respectively). These results suggest that violent protests are the durable component of citizen mobilization following apex corruption scandals. Appendix S10 reports the analogous event

studies estimated separately on the President + Other Apex and Other Non-Apex subsamples of Table 1, for both the OLS and Poisson estimators.

Figure 1. Violent protests increase and peaceful protests decrease in the 120-days after a scandal disclosure.

This figure shows the estimates on event-time bin indicators from the modified version of Equation 1 described in Section 2. Both panels use the ± 120 -day window with 30-day bins; the omitted reference bin is the 30 days immediately preceding the scandal ($w_{s,t} \in [-30, -1]$). Vertical bars are 90% confidence intervals. An observation is a country-scandal-date.

3.3 Heterogeneity by political rank

We have thus far showed that apex corruption scandals cause protests to turn violent, and that the effects persist even four months after a scandal is disclosed. In this section we show that the effects are heterogeneous even within the apex of the political spectrum. To do this, we classify each of our scandals according to the position of the implicated politician. Then, we estimate Equation 1 for each of our scandals individually on its own country's 30-day window (i.e., the scandal-protest datasets described in step (ii) in Section 2), and plot the distribution of point estimates for each of the categories of implicated politicians. Our sample has 45 scandals in which the implicated politician is a president, and within the remaining 131 scandals, 19 implicate Governors and Supreme Court Judges (we call this group "Other Apex"), and 112 implicate Congressmen, lower judiciary, and other lower level officials ("Other Non-apex"). Since some of the scandals show no variation in the outcome, the boxplots show the distribution of effects in the subsample of country-years in which mobilization happens³.

Figure 2 characterizes the heterogeneity of the protest response across the political rank of the implicated official. For violent protests, the median per-scandal effect for Presidents is 0.044 protests per country-day, an order of magnitude larger than the corresponding median for the "Other Apex"

³Our dataset may suffer from underreporting if, e.g., protests happen but less than 50 people take part in them. Under this scenario, the MM dataset would not code a protest occurrence.

(Governors and Supreme Court Judges) category. This latter comparison rests on the subsample of scandals with within-window variation in the outcome—7 Presidential and 8 Other-Apex scandals in the violent-protests panel—so the ratio should be read as descriptive rather than as a precise effect size. Peaceful protests on the other hand show little to no difference in the median effects. The median effect for scandals implicating Presidents is 0.003, while the median effect for scandals implicating Governors or Supreme Court Judges is a 0.045 *decrease*. Scandals implicating Congressmen, lower judiciary, and lower rank officials have median effects of -0.008 and -0.001 on violent and peaceful protests. These results highlight the importance of the “apexness” component of the scandals. Even though corruption in general may be condemned by citizens, it is apex corruption that generates violent mobilization. A potential explanation for our findings is that mobilization rises with the stakes of the scandal: scandals implicating lower level officials are detrimental to democracy but may not warrant violent mobilization as they are potentially less able to affect society at a large scale. Higher level officials—Presidents in particular—, can generate large scale costs to society when engaging in corrupt behavior.

Figure 2. Scandals implicating Presidents cause larger increases in violent protests.

We estimate the OLS post-scandal coefficient of Equation 1 on the ± 30 -day window of the implicated country alone, retaining the day-of-week and month-of-year fixed effects. Each panel summarizes, by box plot, the cross-scandal distribution of those per-scandal coefficients $\hat{\beta}_s$ for the corresponding outcome under the apex partition: President (45 scandals), Other Apex (19 scandals; Governors and Supreme-Court Justices), and Other Non-Apex (112 scandals; members of Congress, lower judiciary, and lower officials). The note inside each panel reports the within-category median of $\hat{\beta}_s$ and the number of scandals contributing to each category. For some scandals the outcome has no within-window variation—i.e., the implicated country recorded no protests of the relevant type throughout the ± 30 -day window—in which case the per-scandal regression cannot identify an effect and the scandal is dropped from the corresponding box plot. The sample period is 2008–2018; Venezuela is excluded.

4 Discussion

The evidence we have presented suggests citizens do not respond uniformly to all types of corruption: they respond sharply, immediately and durably when the implicated official is at the apex of the political spectrum, and they barely respond when the implicated official sits at the lower tier of the hierarchy. Furthermore, the response concentrates on violent protests and persists even after four months. The peaceful margin, which relies more on institutional punishment and change, attenuates over the four-month horizon (and even reverses sign in our Poisson estimates). Our findings underscore the fact that corruption is a tangible behavioral shock to the local (and perhaps even regional) political environment, not just an attitudinal one. The stakes citizens hold in the continuation in office of a corrupt official appear to govern whether citizens mobilize, and how they do so. The joint pattern—a persistent rise in violent protests together with a longer-run attenuation of peaceful protests—is consistent with, though our design does not establish, a shift away from peaceful and toward violent channels when citizens lose confidence in institutional avenues of accountability.

Three additional pieces of evidence reinforce this reading. First, the effect survives modern heterogeneity-robust difference-in-differences estimators—Sun & Abraham, Borusyak-Jaravel-Spiess imputation, and de Chaisemartin & D’Haultfoeuille—under both a scandal-stacked and a country-week staggered-adoption design ([Appendix S13](#)), so it is not an artifact of two-way fixed-effects aggregation. Second, benchmarking against two other high-salience national shocks with plausibly as-good-as-random timing—football match losses and currency depreciations—shows that neither moves violent protests, underscoring that the mobilization response is specific to apex corruption rather than to salient national events in general ([Appendix S11](#)). Third, splitting countries at the median of their 2008 level of democracy, the violent-protest response concentrates in the lower-democracy countries ([Appendix S12](#)), consistent with mobilization rising where institutional avenues of accountability are weaker.

Our findings contribute to three literatures. First, the economics-of-conflict literature has documented that political violence responds to economic shocks ([König et al. 2017](#); [McGuirk and Burke 2020](#); [Dube and Vargas 2013](#); [Besley and Persson 2011](#); [Berman et al. 2011](#); [Rohner et al. 2026](#)). We introduce a *political* shock—public disclosure of apex corruption—and show that it produces mobilization responses of comparable magnitude to the ones caused by economic shocks. Second, the corruption and accountability literature has documented that disclosures of malfeasance change voting behavior ([Ferraz and Finan 2008, 2011a,b](#); [Avis et al. 2018](#); [Arias et al. 2019](#)). The slow electoral horizon has tended to obscure that the same disclosures can have very fast, non-electoral consequences ([Madestam et al. 2013](#); [Bursztyn et al. 2021](#)). Our high-frequency design uncovers a

channel through which apex corruption shapes the political environment in democracies within days of public disclosures, well before subsequent elections come into play. Third, the protest channel is the behavioral complement of the attitudinal evidence from our companion paper (Rivera et al. 2024), which documents that apex corruption scandals erode support for democracy and democratic institutions, and also reduce political participation.

Our results help reconcile part of the mixed results in the existing literature on the political consequences of corruption disclosures. Studies of local level corruption have produced muted estimates of disclosure’s electoral consequences, with some finding modest accountability gains in Brazil and Spain (Ferraz and Finan 2008, 2011a; Avis et al. 2018; Costas-Pérez et al. 2012) and others finding null or even demobilizing effects (Chong et al. 2015; Anduiza et al. 2013; Pavão 2018; Arias et al. 2022). We argue that the dispersion in municipal estimates reflects the limited political stakes at that level. In particular, when the implicated official is one of many municipal officeholders, citizens have weaker incentives to incur the costs of mobilization. Within our sample, scandals implicating Congressmen, lower judiciary and lower rank officials, have median per-scandal effects statistically indistinguishable from zero. Scandals implicating Presidents, on the other hand, have median per-scandal effects an order of magnitude larger than those implicating Governors and Supreme Court Judges—a descriptive comparison that rests on the small subset of scandals with within-window variation in the outcome.

A “salience of stakeholders” view rationalizes this (Acemoglu and Robinson 2006, 2012; Jha 2013; Jha and Shayo 2019; Jha 2022). Citizens’ political behavior responds to the political weight of *what* is being disclosed. Apex corruption, thus, affects citizens’ perceived stakes of the political bargain, particularly when the implicated official is at the apex of the political hierarchy. The contrast between high-stakes presidential scandals and low-stakes lower officials scandals parallels the contrast between high-stakes elections and routine governance in studies of political accountability (Martinez-Bravo et al. 2022), and is consistent with the idea that citizen engagement depends on whether institutions can deliver outcomes (Acemoglu et al. 2019, 2024; Depetris-Chauvin et al. 2020).

Our empirical analyses have some limitations worth noting. Our identification strategy relies on the timing of apex corruption disclosures, not on the timing of the corrupt act itself. If the timing of disclosures is correlated with pre-existing political conditions that affect mobilization (violent or peaceful), our estimates could then be biased. Somewhat reassuringly, the pre-scandal estimates in Figure 1 show no evidence of pre-existing trends in mobilization. A second limitation comes from the fact that the MM dataset is constructed by looking at news sources reporting on mobilization events. Small protests may thus be underreported as they are not big enough to draw media attention, or

protests occurring in geographically remote areas may also be left out. This would induce measurement error in our estimates, but if anything this would bias our estimates toward zero. Relatedly, there is no variation in the outcome around a large share of our scandals, which limits our heterogeneity analysis to the subsample of scandals around which mobilization patterns change. And finally, our scandal sample is limited to Latin American democracies in the 2008–2018 period, thus limiting the external validity of our findings insofar as different regions in the world may mobilize differently in response to corruption scandals. One could also expect different results when shortening/expanding the time scope of the analysis if one believes that the cumulative amount of apex corruption episodes affect the extent to which citizens mobilize.

Supplementary Materials

S1 Scandal classification

Each of the 176 scandals in our event-window panel is manually classified by the position of the implicated politician. Classification proceeds in two steps.

Step 1: raw position. We start from the free-text description of each scandal (fields `official_involved` and the summary paragraph attached to each event ID). A research assistant reads the description and assigns one of five raw position codes:

- **president** — sitting or immediately-former head of state; the scandal implicates the President personally in the corrupt act or in a coverup thereof.
- **governor** — sitting head of a first-order subnational unit (state, department, province).
- **sc_judge_congressman** — either a Supreme Court Justice (constitutional or supreme court) or a sitting national legislator. This raw code is subdivided in Step 2.
- **other_judiciary** — lower-court judges, prosecutors, and members of the judicial administration below the constitutional court.
- **others** — ministers, agency heads, mayors, subnational legislators, and all other public officials not captured above.

The raw codes and each scandal's official description are stored in `scandals_classified.csv`.

Step 2: splitting the `sc_judge_congressman` category. Because the raw code lumps two very different offices (constitutional-court justices and members of Congress) together, we manually verify each such row against the case description and, for the ones in which the implicated official is a Supreme Court justice, tag the scandal's id accordingly. The set of IDs re-tagged as Supreme Court justices, as of 2026-06-27, is 202, NEW26, NEW30, 332, and NEW23. The remaining `sc_judge_congressman` rows are legislators (members of Congress).

Final three-way partition. We then aggregate raw codes into three politically meaningful bins:

- **President** = `president`. *45 scandals.*
- **Other Apex** = `governor` plus the five SC-Justice IDs above. *19 scandals.*
- **Other Non-Apex** = `other_judiciary` + `others` + the remaining `sc_judge_congressman` IDs (Congressmen). *112 scandals.*

This is the “apex partition v2” used in the boxplots of Figure 2 and in the restricted-sample regressions of Sections S4 and S5 and in the pooled interaction regression of Appendix S8. The mapping is implemented in `per_scandal_effects_apex_v2.do` and reused verbatim by every do-file in this Supplementary Materials block.

S2 Table 1 with Poisson QML incidence-rate ratios

Table S1 is the Poisson QML counterpart to the main-text Table 1: same two-panel split (President + Other Apex in Panel A; Other Non-Apex in Panel B), same $\pm 30/\pm 120$ -day windows, same fixed effects and clustering. Poisson is estimated only on the four count outcomes (columns 1–4); the share columns (5–8) are left blank because the incidence-rate ratio has no meaning for a share in $[0, 1]$.

Table S1. Table 1 with Poisson QML incidence-rate ratios.

	± 30 -Day Window		± 120 -Day Window	
	(1)	(2)	(3)	(4)
Violent				
Protests		Peaceful Protests	Violent Protests	Peaceful Protests
<i>Panel A: President + Other Apex</i>				
Post Scandal (IRR)	2.180**	1.138	1.375*	1.083
	(0.660)	(0.556)	(0.253)	(0.303)
Mean (Pre-Scandal Bin)	0.101	0.041	0.054	0.018
Observations	1397	1778	7519	12613
Number of Scandals	28	32	34	53
Pseudo R-squared	0.299	0.170	0.339	0.220
<i>Panel B: Other Non-Apex</i>				
Post Scandal (IRR)	0.875	1.189	1.932*	0.778
	(0.284)	(0.210)	(0.744)	(0.127)
Mean (Pre-Scandal Bin)	0.077	0.176	0.031	0.098
Observations	1884	3763	13604	20728
Number of Scandals	41	64	63	95
Pseudo R-squared	0.339	0.436	0.260	0.322

Poisson QML incidence-rate ratios $\exp(\beta)$ from Equation 1 with delta-method standard errors in parentheses; stars test $H_0 : \beta = 0$ (equivalently, IRR = 1). Panel A: President + Other Apex (64 scandals); Panel B: Other Non-Apex (112 scandals). Columns 1–4 report the four count outcomes; columns 5–8 (share outcomes in the OLS table) are intentionally blank. Standard errors clustered at country $\times$ year $\times$ day-bin. Same fixed effects, sample period, and clustering as Table 1. The Poisson sample is smaller than the OLS sample because `ppmlhdf` drops observations that are either singletons or separated by a fixed effect.

S3 Pooled interaction: (Pres + Other Apex) vs. Other Non-Apex

Table S2 pools the two subsamples of the main Table 1 into a single specification and formally tests whether the post-scandal effect differs between them. Specifically, for each outcome and window we estimate

$$Y_{c(s)t} = \beta_{PA} \text{Post}_{st} \mathbf{1}\{PA_s\} + \beta_{NA} \text{Post}_{st} \mathbf{1}\{NA_s\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t},$$

where $PA_s = \mathbf{1}\{\text{scandal } s \text{ implicates a President or an Other Apex official}\}$ and $NA_s = \mathbf{1}\{\text{scandal } s \text{ implicates an Other Non-Apex official}\}$. The row labeled “ p -value: (Pres+OA) = (ONA)” reports the two-sided p -value from testing $H_0 : \beta_{PA} = \beta_{NA}$.

Table S2. Pooled interaction: (Pres + Other Apex) vs. Other Non-Apex.

	± 30 -Day Window		± 120 -Day Window		Shares (± 30 -Day)		Shares (± 120 -Day)

R-squared	0.169	0.474	0.126	0.300	0.176	0.494	0.129	0.292

OLS estimates of β_{PA} and β_{NA} from the specification above. Sample is restricted to observations belonging to either the President + Other Apex or Other Non-Apex subsamples (i.e., excludes any scandals unclassified in [Appendix S1](#)). Standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. Same fixed effects and sample period as Table 1. Share outcomes are defined in the note to Table 1.

S4 Table 1 restricted to Presidential scandals

Table S3 re-estimates [Equation 1](#) on the subsample of scandals in which the implicated official is a sitting President (45 scandals). Everything else is identical to the main Table 1.

Table S3. Table 1 restricted to Presidential scandals.

	± 30 -Day Window		± 120 -Day Window		Shares (± 30 -Day)		Shares (± 120 -Day)	
	(1) Violent Protests	(2) Peaceful Protests	(3) Violent Protests	(4) Peaceful Protests	(5) Share Violent	(6) Share Peaceful	(7) Share Violent	(8) Share Peaceful
Panel A: OLS								
Post Scandal	0.035* (0.018)	0.006 (0.005)	0.007 (0.008)	-0.003 (0.010)	0.034* (0.018)	0.004 (0.004)	0.006 (0.008)	-0.005 (0.009)
Mean (Pre-Scandal Bin)	0.000	0.015	0.003	0.009	0.000	0.015	0.003	0.009
Observations	2745	2745	10845	10845	2745	2745	10845	10845

Number of Scandals	28	32	34	53				
Pseudo R-squared	0.299	0.170	0.339	0.220				

Panel A reports OLS estimates of β from Equation 1 on eight outcomes (cols. 1–4 counts, cols. 5–8 shares); Panel B reports Poisson QML incidence-rate ratios on the four count outcomes only, with cols. 5–8 blank because IRR has no meaning on a share in $[0, 1]$. Subsample: scandals classified as “President” or “Other Apex” in Appendix S1. Standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. Share outcomes are defined in the note to Table 1. Same fixed effects, sample period, and clustering as Table 1.

S6 Placebo test: randomizing the scandal date within the event window

If the observed effect really begins at the scandal’s public-disclosure date and there is no anticipation, then artificially placing the post-scandal cutoff at a pre-scandal day within the same event window should yield null coefficients. Because the pre-window contains at most $T - 1$ candidate offsets, random draws would repeat the same k many times over 1,000 replications; we instead *enumerate* each offset once. For every $k \in \{-T + 1, \dots, -1\}$ we redefine $\widetilde{\text{Post}}_{st} = \mathbf{1}\{w_{st} \geq k\}$, where w_{st} is the event-time index, and re-estimate the headline OLS specification on the original event-window sample. No country-day is added or removed; only the treatment cutoff is shifted into the pre-scandal window.

Figure S1 plots the resulting series of placebo coefficients $\hat{\beta}(k)$ against k for both outcomes and both windows. The observed β (from Table 1, red horizontal line) sits well above the pre-scandal placebo series for violent protests, consistent with the effect emerging at $k = 0$; for peaceful protests the placebo series and the observed β both hover near zero.

Placebo test by apex-partition subsample

Figures S2 and S3 rerun the same enumerated pre-scandal placebo test separately on the two subsamples of Table 1: President + Other Apex (Panel A) and Other Non-Apex (Panel B). For each subsample the observed $\hat{\beta}$ is the coefficient from the corresponding cell of Table 1, so the placebo series is directly comparable to the headline split estimates.

Figure S1. Placebo test: $\hat{\beta}(k)$ under an enumerated pre-scandal cutoff.

(a) Violent protests, ± 30 -day window.

(b) Violent protests, ± 120 -day window.

(c) Peaceful protests, ± 30 -day window.

(d) Peaceful protests, ± 120 -day window.

For each offset $k \in \{-T + 1, \dots, -1\}$ we replace the treatment indicator by $\widetilde{\text{Post}}_{st} = \mathbf{1}\{w_{st} \geq k\}$ and re-estimate the OLS specification in Equation 1. Each panel plots the resulting point estimate $\hat{\beta}(k)$ against k (gray circles), so each pre-scandal offset is used exactly once. The solid red horizontal line marks the observed $\hat{\beta}$ from Table 1; the dotted line marks zero. The top-right legend reports the rank of the observed $\hat{\beta}$ among the T estimates (placebos plus observed, where 1 is the largest) and the two-sided randomization-inference p -value (share of placebo estimates with $|\hat{\beta}(k)| \geq |\hat{\beta}_{\text{obs}}|$). Standard errors clustered at country $\times$ year $\times$ day-bin. Sample period 2008–2018; Venezuela excluded.

Figure S2. Placebo test on the President + Other Apex subsample.

(a) Violent protests, ± 30 -day window.

(b) Violent protests, ± 120 -day window.

(c) Peaceful protests, ± 30 -day window.

(d) Peaceful protests, ± 120 -day window.

Same construction as [Figure S1](#), restricted to the 64 scandals in the President + Other Apex subsample of [Table 1](#) (Panel A). The solid red horizontal line marks the observed $\hat{\beta}$ from Panel A of [Table 1](#) at the corresponding outcome $\times$ window cell; each gray circle is a placebo cutoff k ; the legend reports the rank of the observed estimate and the two-sided randomization-inference p -value. Sample period 2008–2018; Venezuela excluded.

Figure S3. Placebo test on the Other Non-Apex subsample.

(a) Violent protests, ± 30 -day window.

(b) Violent protests, ± 120 -day window.

(c) Peaceful protests, ± 30 -day window.

(d) Peaceful protests, ± 120 -day window.

Same construction as [Figure S1](#), restricted to the 112 scandals in the Other Non-Apex subsample of [Table 1](#) (Panel B). The solid red horizontal line marks the observed $\hat{\beta}$ from Panel B of [Table 1](#) at the corresponding outcome $\times$ window cell. Sample period 2008–2018; Venezuela excluded.

S7 Randomization inference

We complement the in-window placebo test with a full randomization-inference exercise. In each of 1,000 replications, and for each of the 176 scandals, we draw a placebo disclosure date uniformly at random within the scandal’s original country-year. A draw is rejected whenever its $\pm T$ -day window would contain an actual disclosure date of any scandal in the same country (i.e., whenever $|k - t_{s'}| \leq T$ for some real scandal s' in that country). If no acceptable date is found within the original country-year after 20 attempts, we fall back to an unconditional draw over all 22 panel countries and all dates in 2008–2018, subject to the same overlap check, for up to 30 additional attempts. We then rebuild the $\pm T$ -day event-window panel around the accepted placebo dates and re-estimate the headline OLS specification.

Figure S4 plots the resulting distribution of placebo $\hat{\beta}$ ’s for both outcomes and both windows. The red vertical line marks the observed $\hat{\beta}$ from Table 1; the top-right box reports the two-sided randomization-inference p -value, defined as the share of placebo replications with $|\hat{\beta}_{\text{placebo}}| \geq |\hat{\beta}_{\text{obs}}|$.

Randomization inference by apex-partition subsample

Figures S5 and S6 rerun the same permutation exercise separately on the two subsamples of Table 1: scandals implicating a President or Other Apex official (Panel A) and scandals implicating an Other Non-Apex official (Panel B). Each figure has four subpanels (outcome $\times$ window). The overlap-rejection rule still treats every real scandal date as “occupied” regardless of which subsample it belongs to, so a Pres+OA placebo cannot land within $\pm T$ of an Other Non-Apex real date and vice versa.

Where the observed effect sits in the placebo distribution

An earlier “scandals-as-random” exercise had placed the observed violent-protest effect in the vicinity of the 90th percentile of a placebo distribution built from randomly-timed fake scandals. Table S5 re-expresses the randomization-inference output above in that same percentile language, so the two exercises can be compared directly. For each subsample $\times$ outcome $\times$ window cell it reports the percentile of the observed $\hat{\beta}$ within the placebo distribution (the share of placebo estimates that fall at or below the observed value, in percent) alongside the two-sided randomization-inference p -value. Consistent with the earlier finding, the observed violent-protest effect sits in the upper tail of the placebo distribution, and does so most sharply in the President + Other Apex subsample.

Figure S4. Randomization inference: placebo $\hat{\beta}$ distribution.

(a) Violent protests, ± 30 -day window.

(b) Violent protests, ± 120 -day window.

(c) Peaceful protests, ± 30 -day window.

(d) Peaceful protests, ± 120 -day window.

Each histogram summarizes 1,000 placebo replications. In each replication, and for each scandal, a placebo disclosure date is drawn uniformly at random within the original country-year, rejected if its $\pm T$ -day window would contain a real disclosure date, and redrawn (unconditionally over all countries and 2008–2018 dates after 20 within-country-year attempts) up to 50 total tries. The maroon vertical line marks the observed $\hat{\beta}$ from Table 1, with its value labeled next to the line. The top-right legend reports the two-sided randomization-inference p -value: the share of placebo replications with $|\hat{\beta}_{\text{placebo}}| \geq |\hat{\beta}_{\text{obs}}|$. Sample period 2008–2018; Venezuela excluded.

Figure S5. Randomization inference on the President + Other Apex subsample.

(a) Violent protests, ± 30 -day window.

(b) Violent protests, ± 120 -day window.

(c) Peaceful protests, ± 30 -day window.

(d) Peaceful protests, ± 120 -day window.

Same construction as [Figure S4](#), restricted to the 64 scandals in the President + Other Apex subsample of Table 1 (Panel A). The observed $\hat{\beta}$ is the OLS coefficient from Panel A of Table 1 at the corresponding outcome $\times$ window cell.

Figure S6. Randomization inference on the Other Non-Apex subsample.

(a) Violent protests, ± 30 -day window.

(b) Violent protests, ± 120 -day window.

(c) Peaceful protests, ± 30 -day window.

(d) Peaceful protests, ± 120 -day window.

Same construction as [Figure S4](#), restricted to the 112 scandals in the Other Non-Apex subsample of Table 1 (Panel B). The observed $\hat{\beta}$ is the OLS coefficient from Panel B of Table 1 at the corresponding outcome $\times$ window cell.

Table S5. Percentile of the observed $\hat{\beta}$ in the randomization-inference placebo distribution.

Subsample	Outcome	Window	Percentile	RI (<i>two – sided</i>)
Full sample	Violent	± 30	97.2	0.082
	Violent	± 120	99.8	0.090
	Peaceful	± 30	82.1	0.392
	Peaceful	± 120	18.2	0.379
President + Other Apex	Violent	± 30	100.0	0.000
	Violent	± 120	97.5	0.122
	Peaceful	± 30	68.0	0.741
	Peaceful	± 120	61.5	0.869
Other Non-Apex	Violent	± 30	52.9	0.988
	Violent	± 120	98.5	0.167
	Peaceful	± 30	76.5	0.503
	Peaceful	± 120	23.4	0.478

For each subsample (full sample, President + Other Apex, Other Non-Apex), outcome (violent, peaceful) and window (± 30 , ± 120 days), “Percentile” is $100 \times$ the share of the 1,000 placebo estimates that are less than or equal to the observed $\hat{\beta}$ from Table 1 (a value near 90 reproduces the earlier “~90th percentile” finding). “RI p ” is the two-sided randomization-inference p -value (share of placebo estimates with $|\hat{\beta}_{\text{placebo}}| \geq |\hat{\beta}_{\text{obs}}|$). Both are computed from the same placebo draws that underlie Figures S4–S6. Sample period 2008–2018; Venezuela excluded.

S8 Regression-based hierarchy analysis

Figure 2 in the main text visualizes heterogeneity across the apex partition using the distribution of per-scandal effects. Table S6 reports the pooled-regression analogue. For each outcome and window we estimate

$$Y_{c(s)t} = \beta_{\text{Pres}} \text{Post}_{st} \mathbf{1}\{\text{Pres}_s\} + \beta_{\text{OA}} \text{Post}_{st} \mathbf{1}\{\text{OA}_s\} + \beta_{\text{ONA}} \text{Post}_{st} \mathbf{1}\{\text{ONA}_s\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t},$$

where Pres_s , OA_s , and ONA_s are scandal-level indicators for President, Other Apex, and Other Non-Apex under the v2 partition (Appendix S1). The specification omits a stand-alone Post term, so each coefficient is the estimated average post-scandal effect for that category, rather than a differential relative to a reference. We additionally report the p -values from testing pairwise equality of the three coefficients.

Table S6. Pooled interaction regression: hierarchy of the protest response.

	± 30 -Day Window		± 120 -Day Window		Shares (± 30 -Day)		Shares (± 120 -Day)

Mean (Pre-Scandal Bin)	0.027	0.069	0.020	0.053	0.027	0.061	0.020	0.048
Observations	10736	10736	42657	42657	10736	10736	42657	42657
Number of Scandals	176	176	176	176	176	176	176	176
R-squared	0.173	0.474	0.128	0.300	0.182	0.494	0.131	0.292

OLS estimates of β_{Pres} , β_{OA} , β_{ONA} (Post $\times$ President, Other Apex, Other Non-Apex) from the pooled interaction specification, run on the four count outcomes (cols. 1–4) and the four share outcomes (cols. 5–8) defined in the note to Table 1. Standard errors (in parentheses) are clustered at the country $\times$ year $\times$ day-bin level. Fixed effects, sample period, and clustering are identical to Table 1. Rows labeled “ p -value” report pairwise equality tests across the three category-specific coefficients within each column.

S9 Sensitivity to the event-window width

We re-estimate the headline OLS and Poisson QML specifications of Table 1 at every event-window width in $T \in \{15, 30, 45, \dots, 150\}$ days and plot the point estimate against T with a 90% confidence interval. Figure S7 reports the four panels: OLS β and Poisson QML incidence-rate ratio $\exp(\beta)$, each estimated on violent and peaceful protest counts. The two window widths used in Table 1 ($T = 30$ and

$T = 120$) are highlighted in red; the thick faint horizontal line marks the null (0 for OLS, 1 for the IRR).

Figure S7. Sensitivity of the headline effect to the event-window width.

For each $T \in \{15, 30, 45, \dots, 150\}$ we re-estimate Equation 1 on the event-window panel restricted to $|w_{st}| \leq T$. Panels (a)–(b) plot the OLS point estimate $\hat{\beta}$; panels (c)–(d) plot the Poisson QML incidence-rate ratio $\exp(\hat{\beta})$. Vertical bars are 90% confidence intervals (SE clustered at country $\times$ year $\times$ day-bin, delta-method on the IRR scale). The two markers highlighted in red correspond to $T = 30$ and $T = 120$, the windows reported in Table 1. The thick horizontal line marks the null. Sample period 2008–2018; Venezuela excluded.

Sensitivity by apex-partition subsample

Figures S8 and S9 rerun the same window-width sweep separately on the President + Other Apex and Other Non-Apex subsamples of Table 1. Within each figure, the violent and peaceful panels share the same y-axis range so the null line is aligned and the coefficient magnitudes are directly comparable across the two outcomes.

Figure S8. Window-width sensitivity, President + Other Apex subsample.

Same construction as [Figure S7](#), restricted to the 64 scandals in Panel A of Table 1 (President + Other Apex). Y-axis is shared between the violent and peaceful panels within each estimator.

Figure S9. Window-width sensitivity, Other Non-Apex subsample.

Same construction as [Figure S7](#), restricted to the 112 scandals in Panel B of Table 1 (Other Non-Apex). Y-axis is shared between the violent and peaceful panels within each estimator.

S10 Event studies by apex-partition subsample

The main-text event study (Figure 1) pools all scandals. Figures S10 and S11 rerun the same ± 120 -day, 30-day-bin event study separately on the two subsamples of Table 1 (President + Other Apex; Other Non-Apex), for both the OLS specification (main-text estimator) and the Poisson QML incidence-rate ratio. The reference bin in every panel is the 30 days immediately preceding disclosure. Consistent with Table 1, the post-scandal rise in violent protests is visible in the President + Other Apex subsample and essentially absent in the Other Non-Apex subsample, with no evidence of pre-trends in either.

Figure S10. Event studies by subsample: OLS $\hat{\beta}$, ± 120 -day window (30-day bins).

OLS estimates on event-time 30-day-bin indicators from the modified Equation 1, estimated separately on the President + Other Apex subsample (top row) and the Other Non-Apex subsample (bottom row). Omitted reference bin is the 30 days immediately preceding the scandal. Vertical bars are 90% confidence intervals; SE clustered at country $\times$ year $\times$ day-bin. An observation is a country-scandal-date. Sample period 2008–2018; Venezuela excluded.

Figure S11. Event studies by subsample: Poisson QML incidence-rate ratio, ± 120 -day window (30-day bins).

Poisson QML incidence-rate ratios $\exp(\hat{\beta})$ on event-time 30-day-bin indicators, estimated separately on each subsample (reference bin normalized to an IRR of 1). The dashed horizontal line marks IRR = 1. Vertical bars are 90% confidence intervals obtained by exponentiating the log-scale bounds. Same fixed effects, clustering, and sample as [Figure S10](#).

S11 Benchmarking against football losses and currency depreciations

To gauge the magnitude of the corruption effect, we benchmark it against two other high-salience national shocks whose timing is plausibly as-good-as-random with respect to the protest baseline: national-team football (soccer) match losses and currency depreciation episodes. For each shock we estimate exactly the headline specification of Table 1—same event-window panel, same country-by-year, month-of-year and day-of-week fixed effects, same clustering, same 2008–2018 sample—on the four count outcome $\times$ window cells. Table S7 reports the OLS estimates and Table S8 the Poisson QML incidence-rate ratios. Each table has four panels so that both headline corruption regressions (President + Other Apex; Other Non-Apex) can be read against the football and depreciation benchmarks.

The comparison sharpens the interpretation of the corruption effect: whereas apex corruption scandals produce a large, statistically significant rise in violent protests, neither football losses nor currency depreciations move violent protests in a statistically or economically meaningful way. The apex-corruption shock is thus distinctive among salient national events in its capacity to trigger violent mobilization.

Table S7. Benchmarking the corruption effect: OLS.

Poisson QML incidence-rate ratios $\exp(\beta)$ from Equation 1; stars test $H_0 : \beta = 0$ (IRR = 1). Panels and specification as in Table S7. The Poisson sample is smaller than the OLS sample because `ppmlhdf` drops separated and singleton observations. Sample period 2008–2018; Venezuela excluded.

S12 Heterogeneity by the 2008 level of democracy

If violent mobilization following apex corruption reflects a breakdown of trust in institutional avenues of accountability, the effect should concentrate in countries where those institutions are weaker to begin with. We test this by splitting the panel countries at the median of their *level of democracy* in 2008, measured by V-Dem’s Electoral Democracy Index (v2x_polyarchy) (Coppedge et al. 2024), and interacting the post-scandal indicator with the resulting above-/below-median classification:

$$Y_{c(s)t} = \beta_{\text{High}} \text{Post}_{st} \mathbf{1}\{\text{High}_c\} + \beta_{\text{Low}} \text{Post}_{st} \mathbf{1}\{\text{Low}_c\} + \alpha_d + \lambda_m + \theta_{cy} + \varepsilon_{c(s)t},$$

where High_c (Low_c) indicates a country above (at or below) the 2008 median. The time-invariant level of democracy is absorbed by the country-by-year fixed effects, so only the $\text{Post} \times$ interactions are identified. Table S9 reports the OLS estimates and Table S10 the Poisson QML incidence-rate ratios; the row labeled “ p -value: HIGH = LOW” tests equality of the two interaction coefficients. Consistent with the mechanism, the violent-protest response is concentrated in the lower-democracy countries.

Table S9. Effect by 2008 level of democracy: OLS.

	± 30 -Day Window		± 120 -Day Window		Shares (± 30 -Day)		Shares (± 120 -Day)

Poisson QML incidence-rate ratios $\exp(\beta)$ for the two interaction terms, count outcomes only. Specification, split, fixed effects, clustering, and sample as in Table S9.

S13 Modern staggered difference-in-differences estimators

Our headline design compares within-country pre- and post-scandal outcomes with country-by-year, month, and day-of-week fixed effects. Because scandals are staggered in calendar time, a two-way fixed-effects (TWFE) estimator could in principle be contaminated by “forbidden comparisons” between newly- and already-treated units (de Chaisemartin and D’Haultfoeuille 2024; Goodman-Bacon 2021). We therefore re-estimate the effect with three heterogeneity-robust estimators—Sun & Abraham (SA) (Sun and Abraham 2021), Borusyak, Jaravel & Spiess (BJS, imputation) (Borusyak et al. 2024), and de Chaisemartin & D’Haultfoeuille (dCDH) (de Chaisemartin and D’Haultfoeuille 2024)—against a TWFE OLS baseline, under two research designs.

Design 1 (main comparable): stacked by scandal. The design closest to our main event-window specification is a Cengiz-style stack (Cengiz et al. 2019): for each scandal we take the treated country’s ± 30 -day (3-day-bin) window together with every country that has no scandal of any type in that window as a clean control cohort, and pool the stacks. This retains all scandals and switches treatment on at event-bin 0. Table S11 reports the static post-scandal coefficient from each estimator, split into the President + Other Apex (Panel A) and Other Non-Apex (Panel B) subsamples; Figure S12 overlays the four estimators’ event-study paths for violent protests.

Design 2 (additional): country-week first-scandal adoption. As a complementary check we collapse the data to a balanced country-week panel and define treatment as a country’s *first* scandal week, which lets each estimator use its native never-treated control group (the four countries with no scandal). Table S12 reports the analogous split estimates and Figure S13 the event-study paths. Because this design uses only the first scandal per country, it is less comparable to the main specification but provides an independent, staggered-adoption robustness check.

Across both designs and all three modern estimators, the post-scandal increase in violent protests in the President + Other Apex subsample is of the same sign and broad magnitude as the TWFE and headline estimates, while the Other Non-Apex subsample remains flat—indicating that the main result is not an artifact of TWFE aggregation. (Outcomes are the Mass-Mobilization counts: “Violent Protests” = `mm_violent`, “Non-violent Protests” = `mm_nonviolent`, matching `num_violent_MM` / `num_peaceful_MM` in Table 1.)

Table S11. Modern DiD estimators, stacked-by-scandal design.
